We present a model for dihadron fragmentation functions, describing the fragmentation of a quark into two unpolarized hadrons. We tune the parameters of our model to the output of the PYTHIA event generator for two-hadron semi-inclusive production in deep inelastic scattering at HERMES. Once the parameters of the model are fixed, we make predictions for other unknown fragmentation functions and for a single-spin asymmetry in the azimuthal distribution of $\pi^+\pi^-$ pairs in semi-inclusive deep inelastic scattering on a transversely polarized target at HERMES and COMPASS. Such asymmetry could be used to measure the quark transversity distribution function.

I. INTRODUCTION

Dihadron Fragmentation Functions (DiFF) describe the probability that a quark hadronizes into two hadrons plus anything else, i.e. the process $q \rightarrow H_1 H_2 X$. They can appear in any process where hadronization is involved, in particular in lepton-lepton, lepton-hadron and hadron-hadron collisions producing final-state hadrons. They carry information that is not accessible to single-hadron fragmentation functions, but on the other hand they are more complex to study and to measure.

Unpolarized DiFF were introduced for the first time by Konishi, Ukawa and Veneziano [1]. Their evolution equations have been studied in Refs. [2, 3] and more recently reanalyzed in Refs. [4, 5, 6]. All these studies focused on the probability of producing two hadrons with energy fractions $z_1$ and $z_2$ by integrating over the invariant mass of the produced pair. However, it is fair to say that the only experimental information related to unpolarized DiFF consists of invariant mass spectra of hadron pairs produced in $e^+e^-$ annihilation [7, 8, 9], Semi-Inclusive Deep-Inelastic Scattering (SIDIS) [10, 11, 12] and proton-proton collisions [13, 14, 15]. Recently, it has been suggested to use DiFF as tools to investigate the in-medium effects in heavy-ion collisions [5, 6, 15, 16, 17]. To address this and other issues, it is necessary to improve our knowledge of unpolarized DiFF in vacuum.

DiFF can be used also for spin studies. In particular, they can act as analyzers of the spin of the fragmenting quark [18, 19, 20, 21, 22] and they can be used to study vector meson polarization [23, 24, 25, 26]. The definition and properties of all possible DiFF for two unpolarized detected hadrons have been presented in Ref. [27] up to leading-twist, and in Ref. [28] up to subleading twist integrated over the transverse component of the center-of-mass (cm) momentum of the hadron pair. Despite the wealth of observables related to polarized DiFF, experimental information is limited [29, 30, 31].

At present, the most important application of polarized DiFF appears to be the measurement of the quark transversity distribution in the nucleon. This function, $h_1$, represents the probabilistic distribution of transversely polarized partons inside transversely polarized hadrons, and is a missing cornerstone to complete the knowledge of the leading-order (spin) structure of the nucleon (for a review see Ref. [32]). Being a chiral-odd function, $h_1$ needs to be combined with another chiral-odd soft function. The simplest possibility is to consider double-spin asymmetries in polarized Drell-Yan processes [33]. This option is under investigation at BNL using high-energy polarized proton-proton collisions [34, 35] and could be studied also at GSI using polarized proton-antiproton collisions [36, 37, 38, 39].

Another possibility is to measure Single-Spin Asymmetries (SSA) in the SIDIS production of a pion on transversely polarized targets. Recent data have been released using proton [40, 41] and deuteron [42] targets. Their interpretation advocates the so-called Collins effect [43], by which a leading-twist contribution to the cross section appears where $h_1$ is convolved with the Collins function $H_1^\perp$, a fragmentation functions that describes the decay probability of a
transversely polarized quark into a single pion. However, extracting $h_1$ from SSA data requires the cross section to depend explicitly upon the transverse momentum of the detected pion with respect to the photon axis. This fact brings in several complications, including the possible overlap of the Collins effect with other competing mechanisms and more complicated factorization proofs and evolution equations.

Semi-inclusive production of two hadrons offers an alternative way to access transversity, where the chiral-odd partner of transversity is represented by the DiFF $H_1^T$, which relates the transverse spin of the quark to the azimuthal orientation of the two-hadron plane. This function is at present unknown. Very recently, the HERMES collaboration has reported measurements of the asymmetry containing the product $h_1 H_1^T$. The COMPASS collaboration has also presented analogous preliminary results. In the meanwhile, the BELLE collaboration is planning to measure the fragmentation functions in the near future.

In this context, it seems of great importance to devise a way to model DiFF. From the theoretical side, this can help understanding what are the essential building blocks and mechanisms involved in dihadron fragmentation. It can also provide a guidance for fits to data and further phenomenological studies. From the experimental side, a model could be useful to study the effects of cuts and acceptance, to estimate the size of observables in different processes and kinematical regimes. Our work is not the first one in this direction. The model presented here is close to the one discussed in Ref. However, for the first time we are able to fix the parameters by comparing our unpolarized DiFF $D_1$ with the output of the PYTHIA event generator tuned for HERMES kinematics. In Sec. V, we show numerical predictions for the polarized DiFF $H_1^T$ and the related SSA involving the transversity distribution $h_1$.

The paper is organized as follows. In Sec. II we review the basic formalism of DiFF and of SIDIS cross section for two-hadron production. In Sec. III we describe our model for the fragmentation of a quark into two unpolarized hadrons and give analytic results for DiFF calculated in this model. In Sec. IV we fix the parameters of the model by comparing it to the output of the PYTHIA event generator tuned for HERMES kinematics. In Sec. V we show numerical predictions for the DiFF and for the above-mentioned SSA in the kinematics explored by the HERMES and COMPASS collaborations. Finally, in Sec. VI we draw some conclusions.

II. BASICS OF DIHADRON FRAGMENTATION FUNCTIONS

Dihadron Fragmentation Functions are involved in the description of the fragmentation process $q \to \pi^+ \pi^- X$. The quark has momentum $k$. The two pions have masses $m_\pi = 0.140$ GeV, momenta $P_1$ and $P_2$, respectively, and invariant mass $M_h$ (considered to be much smaller than the hard scale of the process, e.g., the virtuality of the photon, $Q$, in SIDIS). We introduce the vectors $P_h = P_1 + P_2$ and $R = (P_1 - P_2)/2$. We describe a 4-vector $a$ as $(a^-, a^+, a^x, a^y)$, i.e. in terms of its light-cone components $a^\pm = (a^0 \pm a^3)/\sqrt{2}$ and its transverse spatial components. We introduce the light-cone fraction $z = P_h^- / k^-$ and the polar angle $\theta$, being the angle between the direction of $P_1$ in the pair’s center of mass and the direction of $P_h$ in the lab frame, so that the relevant momenta can be written as

\begin{equation}
    k^\mu = \left[ P^-_h / z, \frac{z(k^2 + \vec{k}_T^2)}{2P^-_h}, k_T^x, k_T^y \right],
\end{equation}

\begin{equation}
    P_h^\mu = \left[ P^-_h, \frac{M_h^2}{2P^-_h}, 0, 0 \right],
\end{equation}

\begin{equation}
    R^\mu = \left[ |\vec{R}|P^-_h \cos \theta, -\frac{|\vec{R}|M_h}{2P^-_h} \cos \theta, R_T^x, R_T^y \right] = \left[ |\vec{R}|P^-_h \cos \theta, -\frac{|\vec{R}|M_h}{2P^-_h} \cos \theta, |\vec{R}| \sin \theta \cos \phi_R, |\vec{R}| \sin \theta \sin \phi_R \right],
\end{equation}

where

\begin{equation}
    |\vec{R}| = \frac{M_h}{2} \sqrt{1 - \frac{4m^2_\pi}{M_h^2}},
\end{equation}

\begin{footnote}
Note that there is a misprint in the expressions for $|\vec{R}|$ in Eq. (27) of Ref. and in Eq. (23) of Ref.
\end{footnote}
and $\phi_R$ is defined later in Eq. (13) (see also Fig. 1). It is useful to compute the scalar products

$$P_h \cdot R = 0,$$

$$P_h \cdot k = \frac{M_h^2}{2z} + z \frac{k^2 + |k_T|^2}{2},$$

$$R \cdot k = \left( \frac{M_h}{2z} - z \frac{k^2 + |k_T|^2}{2 M_h} \right) |\vec{R}| \cos \theta - \vec{k}_T \cdot \vec{R}_T.$$

Fragmentation functions are extracted from the correlation function [57]

$$\Delta^q(z, \cos \theta, M_h^2, \phi_R) = \frac{z |\vec{R}|}{16 M_h} \int d^2 k_T \; dk^+ \; \Delta^q(k; P_h, R) \bigg|_{k^- = P_h^- / z},$$

where [28, 56]

$$\Delta^q(k; P_h, R)_{ij} = \sum_X \int \frac{d^4 \xi}{(2\pi)^4} \; e^{i k \cdot \xi} \langle 0 | U^+_n(\xi) \psi^q_i(\xi) | P_h, R; X \rangle \langle P_h, R; X | \bar{\psi}^q_i(0) U^+_n(0, -\infty) | 0 \rangle.$$  \hspace{1cm} (8)

Since we are going to perform the integration over the transverse momentum $\vec{k}_T$, the Wilson lines $U$ can be reduced to unity using a light-cone gauge.

The only fragmentation functions surviving after $\vec{k}_T$-integration are [27, 55]

$$D^q_i(z, \cos \theta, M_h^2) = 4\pi \text{Tr} [\Delta^q(z, \cos \theta, M_h^2, \phi_R) \gamma^-],$$

$$\frac{\phi_{ij} R_{Tj}}{M_h} H^q_{1,q}(z, \cos \theta, M_h^2) = 4\pi \text{Tr} [\Delta^q(z, \cos \theta, M_h^2, \phi_R) i \sigma^{-} \gamma_5].$$  \hspace{1cm} (10)

These functions can be expanded in the relative partial waves of the pion pair system. Truncating the expansion at the $p$-wave level we obtain [55]

$$D^q_i(z, \cos \theta, M_h^2) \approx D^q_{1,oo}(z, M_h^2) + D^q_{1,ol}(z, M_h^2) \cos \theta + D^q_{1,U}(z, M_h^2) \frac{1}{4} (3 \cos^2 \theta - 1),$$

$$H^q_{1,q}(z, \cos \theta, M_h^2) \approx H^q_{1,oo}(z, M_h^2) + H^q_{1,ol}(z, M_h^2) \cos \theta.$$

The fragmentation function $D^q_{1,oo}$ can receive contributions from both $s$ and $p$ waves, but not from the interference between the two, $D^q_{1,ol}$ and $H^q_{1,ol}$ originate from the interference of $s$ and $p$ waves, $D^q_{1,U}$ comes from polarized $p$ waves, and $H^q_{1,U}$ originates from the interference of two $p$ waves with different polarization.

Our model can make predictions for the above fragmentation functions as well as for transverse-momentum-dependent fragmentation functions, which we do not consider in this Section. However, we will focus our attention mainly on the functions $D^q_{1,oo}$ and $H^q_{1,ol}$ because of their relevance for transversity measurements in SIDIS [14, 21, 47, 57].

Let’s consider in fact the SIDIS process $l p \to l' \pi^\mp \pi^- X$, where $l$ and $l'$ are the momenta of the lepton before and after the scattering and $q = l - l'$ is the momentum of the virtual photon. We consider the cross section differential in $dM_h^2$, $d\phi_R$, $dz$, $dx$, $dy$, $d\phi_S$, where $z$, $x$, $y$ are the usual scaling variables employed in SIDIS, and the azimuthal angles are defined so that (see Fig. 1)

$$\cos \phi_S = \frac{(\vec{q} \times \vec{l})}{|\vec{q} \times \vec{l}|}, \quad (\vec{q} \times \vec{S}),$$

$$\sin \phi_S = \frac{(\vec{l} \times \vec{S}) \cdot \vec{q}}{|\vec{l} \times \vec{S}| |\vec{q}|},$$

$$\cos \phi_R = \frac{(\vec{q} \times \vec{l})}{|\vec{q} \times \vec{l}|}, \quad (\vec{q} \times \vec{R}_T),$$

$$\sin \phi_R = \frac{(\vec{l} \times \vec{R}_T) \cdot \vec{q}}{|\vec{l} \times \vec{R}_T| |\vec{q}|},$$

where $\vec{q} = \vec{q} / |\vec{q}|$ and $\vec{R}_T$ is the component of $R$ perpendicular to $P_h$.

2 The definition of the angles is consistent with the so-called Trento conventions [58].
When the target is transversely polarized, we can define the following cross section combinations

\[ d^{\phi}\sigma_{UU} = \frac{d^{\phi}\sigma^{\perp} + d^{\phi}\sigma^{\perp}}{2} = \sum_{q} \frac{a^{2}e_{q}^{2}}{\pi yQ^{2}} \left( 1 - y + y^{2}/2 + y^{2}\gamma^{2}/4 \right) f_{1}(x) D_{1,oo}(z, M_{h}^{2}) \]
\[ d^{\phi}\sigma_{UT} = \frac{d^{\phi}\sigma^{\perp} - d^{\phi}\sigma^{\perp}}{2} = - \sum_{q} \frac{a^{2}e_{q}^{2}}{4yQ^{2}} \left( 1 - y - y^{2}\gamma^{2}/4 \right) \sin(\phi_{R} + \phi_{S}) h_{1}(x) \frac{f_{1}(x)}{M_{h}} H_{1,oo}(z, M_{h}^{2}) \]

where \( \alpha \) is the fine structure constant, \( \gamma = 2M x/Q \), and \( M \) is the mass of the target. These expressions are valid up to leading twist only. Subleading contributions are described in Ref. [28]. In particular, they give rise to a term proportional to \( \cos \phi_{R} \) in \( d^{\phi}\sigma_{UU} \) and a term proportional to \( \sin \phi_{S} \) in \( d^{\phi}\sigma_{UT} \). Corrections at order \( \alpha_{S} \) were partially studied in Ref. [4], but further work is required.

We can define the asymmetry amplitude

\[ A^{\sin(\phi_{R} + \phi_{S})}(x, y, z, M_{h}^{2}) = \frac{1}{\sin(\phi_{R} + \phi_{S})} \frac{d^{\phi}\sigma_{UT}}{d^{\phi}\sigma_{UU}} = \frac{1 - y - y^{2}\gamma^{2}/4}{1 + y^{2}/2 + y^{2}\gamma^{2}/4} \frac{\pi \frac{f_{1}(x)}{M_{h}} \sum_{q} e_{q}^{2} h_{1}^{q}(x) H_{1,oo}(z, M_{h}^{2})}{4 \sum_{q} e_{q}^{2} f_{1}^{q}(x) D_{1,oo}(z, M_{h}^{2})} \]

Note that we avoided simplifying the prefactors because numerator and denominator are usually integrated separately over some of the variables.

### III. Fragmentation Functions in a Spectator Model

We aim at describing the process \( q \rightarrow \pi^{+}\pi^{-} X \) at invariant mass \( M_{h} \lesssim 1.3 \text{ GeV} \). To have an idea of the prominent channels contributing to this process, we examined the output of the PYTHIA event generator [53] tuned for HERMES [54], which well reproduces the measured events at HERMES. Further details concerning the event generator’s output will be discussed in the next section. Fig. 2 shows the number of counted dihadron pairs in bins of \( M_{h} \) (200 bins from 0.3 to 1.3 GeV). The total amount of events is 2667889.

A few prominent channels contribute to this process:

1. \( q \rightarrow \pi^{+}\pi^{-} X_{1} \): fragmentation into an “incoherent” \( \pi^{+}\pi^{-} \) pair that we will call, in the following, “background”;
2. \( q \rightarrow \rho \ X_{2} \rightarrow \pi^{+}\pi^{-} X_{2} \): fragmentation into a \( \rho \) resonance decaying into \( \pi^{+}\pi^{-} \), responsible for a peak at \( M_{h} \sim 770 \text{ MeV} \) (14.81%);
3. \( q \rightarrow \omega \ X_{3} \rightarrow \pi^{+}\pi^{-} X_{3} \): fragmentation into a \( \omega \) resonance decaying into \( \pi^{+}\pi^{-} \), responsible for a small peak at \( M_{h} \sim 782 \text{ MeV} \) (0.31%).

---

3 The definition of the angles in Eqs. (14,15) is consistent with the so-called Trento conventions [55] and it is the origin of the minus sign in Eq. (17) with respect to Eq. (43) of Ref. [55] (compare \( \phi_{R} \) and \( \phi_{S} \) in Fig. 1 with the analogue ones in Fig. 2 of Ref. [55]).
4. \( q \rightarrow \omega \ X'_4 \rightarrow \pi^+\pi^- X_4 \) with \( X_4 = \pi^0 \ X'_4 \): fragmentation into a \( \omega \) resonance decaying into \( \pi^+\pi^-\pi^0 \) (\( \pi^0 \) unobserved), responsible for a broad peak around \( M_8 \sim 500 \text{ MeV} \) (8.65%);

5. \( q \rightarrow \eta \ X'_5 \rightarrow \pi^+\pi^- X_5 \) with \( X_5 = \lambda' \ X'_5 \): fragmentation into a \( \eta(547) \) or \( \eta'(958) \) decaying into \( \pi^+\pi^-\lambda' \) (\( \lambda' \) unobserved), responsible for a peak around \( M_8 \sim 350 \text{ MeV} \) (2.05%);

6. \( q \rightarrow K^0 \ X_6 \rightarrow \pi^+\pi^- X_6 \): fragmentation into a \( K^0 \) resonance decaying into \( \pi^+\pi^- \), responsible for a narrow peak at \( M_8 \sim 498 \text{ MeV} \) (3.41%).

On top of these, there could be the presence of two other channels:

7. \( q \rightarrow \sigma \ X_7 \rightarrow \pi^+\pi^- X_7 \): fragmentation into the largely debated \( \sigma \) resonance (see, e.g., Ref. [59]) decaying into \( \pi^+\pi^- \), which could be responsible for a very broad peak anywhere between 400 and 1200 MeV;

8. \( q \rightarrow f_0 \ X_8 \rightarrow \pi^+\pi^- X_8 \): fragmentation into a \( f_0 \) resonance decaying into \( \pi^+\pi^- \), which should give rise to a peak at \( M_8 \sim 980 \text{ MeV} \), not evident in the output of PYTHIA.

In our model, we considered only channels 1 to 6. All events not belonging to channels 2 to 6 were included in channel 1, which then contains 70.77% of the total events.

We work in the framework of a “spectator” model for the fragmentation process: for \( q \rightarrow \pi^+\pi^- X \), the sum over all possible intermediate states \( X \) is replaced by an effective on-shell state – the spectator – whose quantum numbers are in this case the same as the initial quark and whose mass is one of the parameters of the model. In principle, different channels could produce spectators with different masses. Moreover, each channel could end up into more than one possible spectator [60]. For sake of simplicity, here we consider just a single spectator for all channels. We shall denote its mass as \( M_s \) and its momentum as \( P_s \). The choice of using the same spectator for all channels implies in particular that the fragmentation amplitudes of all channels can interfere with each other maximally. In reality, it is plausible that only a fraction of the total events ends up in the same spectator and can thus produce interference effects.

Pions in channels 2 and 3 are obviously produced in relative \( p \) wave, since they come from the decay of a vector meson. In channel 4, each charged pion can be in a relative \( p \) wave with respect to the other one or to \( \pi^0 \), the net result being that there is a fraction of \( \pi^+\pi^- \) pairs that is produced in a relative \( s \) wave. In the following, we will neglect this fraction and assume that all charged pairs are produced in \( p \) wave; at present we don’t have enough information to discriminate the two contributions. This assumption is most probably inadequate and would lead to an overestimate of the contribution of channel 4 to the final single spin asymmetry.

We further assume that all pions in channel 1 are produced in \( s \) wave. It is possible that a fraction of the background events are also produced in \( p \) wave. However, such a fraction cannot be too big, as it would give rise to interference effects that would distort the shape of the \( p \) meson peak. It is actually known that such a distortion can indeed occur, but also that it is not big [3, 61]. We think that this point deserves further attention, but should not change the main features of our results.
indicating the quark flavor and calculate the fragmentation functions for suppress the contributions from high quark virtualities \[6, 2\]. Other possibilities can be considered, e.g., dipole for factors \[47, 52\], or sharp cutoffs \[63\].

Isospin symmetry implies that the fragmentation correlator for \(s\) wave contribution, the terms with vertex \(F^s\) to the \(p\)-wave contribution. The exponential form factors suppress the contributions from high quark virtualities \[62\]. Other possibilities can be considered, e.g., dipole form factors \[47, 52\], or sharp cutoffs \[63\].

We model the correlation function in the following way (see Fig. 3):

\[
\Delta^q(k, P_h, R) = \frac{1}{(2\pi)^4} \frac{(\frac{q}{2} + m)}{k^2 - m^2} \left( F^{s*} e^{-\frac{k^2}{2\pi^2}} + F^{p*} e^{-\frac{k^2}{2\pi^2}} R \right) \left( \frac{q}{2} - P_h + M_s \right) \times \left( F^s e^{-\frac{k^2}{2\pi^2}} + F^p e^{-\frac{k^2}{2\pi^2}} R \right) \left( \frac{q}{2} + m \right) 2\pi \delta((k - P_h)^2 - M_s^2). \tag{19}
\]

Isospin symmetry implies that the fragmentation correlator for \(u \rightarrow \pi^+\pi^- X\) is the same as for \(d \rightarrow \pi^+\pi^- X\), \(d \rightarrow \pi^-\pi^+ X\), \(\bar{d} \rightarrow \pi^-\pi^+ X\). Therefore, the result for \(d\) and \(\bar{d}\) quarks can be obtained from the result for \(u\) quark by simply changing the sign of \(\bar{R}\), i.e. changing \(\theta \rightarrow \pi - \theta\) and \(\phi \rightarrow \phi + \pi\). From now on we will drop the superscript indicating the quark flavor and calculate the fragmentation functions for \(u \rightarrow \pi^+\pi^- X\). The terms with vertex \(F^s\) refer to the \(s\)-wave contribution, the terms with vertex \(F^p\) to the \(p\)-wave contribution. The exponential form factors suppress the contributions from high quark virtualities \[62\]. Other possibilities can be considered, e.g., dipole form factors \[47, 52\], or sharp cutoffs \[63\].

Inserting Eq. (19) into Eq. (8), we get

\[
\Delta(z, \cos \theta, M_h^2, \phi_R) = \frac{|\bar{R}|}{128 \pi^2 M_h} \left( \frac{z}{2(1 - z) P_h} \right)^2 \int d|\vec{k}_T|^2 \left[ F^{s*} e^{-\frac{2k^2}{2\pi^2}} \left( \frac{q}{2} + m \right) \left( \frac{q}{2} - P_h + M_s \right) \left( \frac{q}{2} + m \right) \right] + |F^p|^2 e^{-\frac{2k^2}{2\pi^2}} \left( \frac{q}{2} + m \right) R \left( \frac{q}{2} - P_h + M_s \right) \left( \frac{q}{2} + m \right) + F^{s*} F^p e^{-\frac{2k^2}{2\pi^2}} \left( \frac{q}{2} + m \right) R \left( \frac{q}{2} - P_h + M_s \right) \left( \frac{q}{2} + m \right) + F^s F^{p*} e^{-\frac{2k^2}{2\pi^2}} \left( \frac{q}{2} + m \right) R \left( \frac{q}{2} - P_h + M_s \right) \left( \frac{q}{2} + m \right) \right], \tag{20}
\]

with \(k^2\) fixed by the on-shell condition of the spectator \[52\], i.e.,

\[
k^2 = \frac{z}{1 - z} |\vec{k}_T|^2 + \frac{M_s^2}{1 - z} + \frac{M_h^2}{z}. \tag{21}
\]

The first and second lines of Eq. (20) describe the pure \(s\) and \(p\)-wave contributions and, as such, they are the only ones that can contribute to the functions \(D_{1,oo}, D_{1,ll}\) of Eq. (12) and \(H_{1,ll}^q\) of Eq. (13), while the third and fourth lines describe the \(sp\) interference and they contribute to the functions \(D_{1,ol}\) and \(H_{1,ol}^q\).

For convenience, we introduce the function

\[
L^2(z, M_h^2) = \frac{1 - z}{z^2} M_h^2 + \frac{1}{z} M_s^2 - \frac{1 - z}{z} m^2. \tag{22}
\]

This function has to be always positive for kinematical reasons.
We obtain the following result for the unpolarized fragmentation function

\[
D_{1,oo}(z, M_h^2) = \frac{z|\bar{R}|}{16\pi M_h} |F^p|^2 e^{-\frac{2m^2}{\Lambda^2_{sp}}} \left(\frac{1 + 2}{z} \frac{M_h^2 - (m + M_s)^2}{z \Lambda^2_{sp}}\right) \Gamma\left(0, \frac{2z L^2}{(1-z) \Lambda^2_p}\right)
\]

\[
- \frac{1 - z}{z^2} M_h^2 - (m + M_s)^2 e^{-\frac{2z L^2}{(1-z) \Lambda^2_p}}
\]

\[
+ \frac{z|\bar{R}|}{16\pi M_h} |F^p|^2 e^{-\frac{2m^2}{\Lambda^2_{sp}}} \frac{1}{3M_h^2} \left(2 M_h^2 + \frac{2 - z}{z} (m^2 - M_s^2)\right) \Gamma\left(0, \frac{2z L^2}{(1-z) \Lambda^2_p}\right)
\]

\[
+ \frac{1}{2z^2 L^2} \left(\frac{1 - z}{z} \frac{M_s^2}{(M_h - z m^2)}\right) \Lambda^2_p
\]

\[
- 2 \left(M_h^2 - (m - M_s)^2\right) (2 M_h^2 + (m + M_s)^2) e^{-\frac{2z L^2}{(1-z) \Lambda^2_p}}
\]

The incomplete \(\Gamma\) function – typically appearing in model calculations with exponential form-factors \[62\] – is defined as \(\Gamma(0, z) \equiv \int_0^\infty e^{-t} \, dt\). The first term of the fragmentation function can be identified with the pure s-wave contribution, also called \(D_{1,oo}^s/4\) in Ref. \[55\], and the second one with the pure p-wave contribution, also called \(3 D_{1,oo}^p/4\).

We give here the results also for the other functions appearing in Eq. \[12\]:

\[
D_{1,0d}(z, M_h^2) = \frac{z|\bar{R}|}{16\pi M_h} 2 \text{Re}(F^{**}F^p) e^{-\frac{2m^2}{\Lambda^2_{sp}}} \frac{|\bar{R}|}{z^2 M_h} \left(\frac{1 - z}{z} \frac{(2 - z) M_h^2 - z (m^2 - M_s^2)}{L^2} e^{-\frac{2z L^2}{(1-z) \Lambda^2_p}}\right)
\]

\[
- \left(2 (m + M_s) \frac{(2 - z) M_h^2 - z (m^2 - M_s^2)}{\Lambda^2_{sp}} + z (m + (1-z) M_s)\right) \Gamma\left(0, \frac{2z L^2}{(1-z) \Lambda^2_p}\right)
\]

\[
D_{1,1d}(z, M_h^2) = \frac{27}{16} D_{1,oo}^p(z, M_h^2) + \frac{z|\bar{R}|}{16\pi M_h} |F^p|^2 e^{-\frac{2m^2}{\Lambda^2_{sp}}} \frac{9}{4 z^3 \Lambda^2_p} \left\{\left(1 - z\right) \frac{L^2}{2z} \Lambda^2_p e^{-\frac{2z L^2}{(1-z) \Lambda^2_p}} - \Gamma\left(0, \frac{2z L^2}{(1-z) \Lambda^2_p}\right)\right\}
\]

\[
\times \left(2 M_h^2 (2 - 2z + z^2) + 4z^2 m M_s - 2z (2 - z) (m^2 - M_s^2)\right) - z \Lambda^2_p (2 - 2z + z^2) \Gamma\left(0, \frac{2z L^2}{(1-z) \Lambda^2_p}\right)
\]

\[
\right)\}
\]

where \(2/\Lambda^2_{sp} = 1/\Lambda^2_x + 1/\Lambda^2_y\).

For the interference fragmentation function \(H_{1,0d}^q\) we obtain

\[
H_{1,0d}^q(z, M_h^2) = -\frac{z|\bar{R}|}{16\pi M_h} 2 \text{Im}(F^{**}F^p) e^{-\frac{2m^2}{\Lambda^2_{sp}}} \frac{M_h}{z^2} \left[\frac{1 - z}{z} \frac{M_h^2 - z^2 m^2}{L^2} e^{-\frac{2z L^2}{(1-z) \Lambda^2_p}}\right]
\]

\[
- \left(2 M_h^2 - z^2 m^2\right) \Gamma\left(0, \frac{2z L^2}{(1-z) \Lambda^2_p}\right)
\]

The interference function \(H_{1,0d}^q\) vanishes in our model, since it would be proportional to \(\text{Im}(F^p F^p)\). It would be necessary to have other sources of nontrivial phases in the amplitudes for p wave production, as the ones given by loop corrections \[21\].

The vertices \(F^s\) and \(F^p\) are essential ingredients to reproduce the correct invariant-mass behavior and to produce the imaginary parts required for the generation of T-odd fragmentation functions. When no resonance is present, we assume the vertices to be real. When resonances are present, the vertex includes the resonance propagator and contains therefore real and imaginary parts. We assume in our calculation that the s-wave background is free of resonances and thus is purely real (at tree level). This is one of the main assumptions we make in the present work and has critical consequences on the invariant-mass behavior of the fragmentation functions \(D_{1,0d}\) and \(H_{1,0d}^q\). As can be readily seen from Eqs. \[24\] and \[20\], assuming \(F^s\) to be real implies that \(D_{1,0d}\) is proportional to \(\text{Re}(F^p)\) and \(H_{1,0d}^q\) is proportional to \(\text{Im}(F^p)\).
At this point it is worthwhile to make a comparison with the results presented in the literature in the past. In Ref. 21, the necessary phase difference between $s$ and $p$ waves was taken from $\pi\pi$ phase shifts in elastic scattering data 65. No hypothesis was made on the invariant-mass behavior of the $s$ and $p$ amplitudes, i.e., on the fragmentation mechanism. The main assumption was that the interference pattern occurring in the fragmentation process, where the initial state is a quark and the final state is composed of many hadrons, is supposed to be the same as in $\pi\pi$ scattering, where initial and final states are simply two pions. In particular, the prediction of Ref. 21 changes sign close to the $\rho$ mass. The effect is in fact proportional to the sum of the real part of the $\rho$ resonance times the imaginary part of the $\sigma$ plus the real part of the $\sigma$ times the imaginary part of the $\rho$. Both real parts change sign close to the $\rho$ mass. On the contrary, in our approach we neglect the contribution of the $\sigma$ and we take a purely real $s$-wave background, but we try to take into account in a collective manner all other ways in which pion pairs can be produced in a semi-inclusive fragmentation process.

A different model prediction was also presented in Ref 17. In that model, the $s$-wave amplitude was modeled as a sequence of two single-pion emissions and was purely real, while the $p$-wave amplitude contained only the $\rho$ decay, therefore having a predictive power limited to invariant masses around the $\rho$ resonance. The $s-p$ phase difference followed from the presence of an imaginary part in the meson propagator. The parameters of the model were fixed using theoretical arguments, since no experimental input was available as a comparison. As already pointed out, the present work is similar to Ref 17, but the $s$-wave amplitude is modeled by means of an effective real vertex and the $p$-wave amplitude contains contributions from the $\rho$ and the $\omega$ mesons. Last but not least, the parameters of the model are fixed by fitting the output of the PYTHIA Monte Carlo generator, which is known to reproduce very well the unpolarized data.

Our ansatz for the vertices is

$$F^s = f_s,$$

$$F^p = f_p \frac{(M_h^2 - M_s^2) - i \Gamma_p M_p}{(M_h^2 - M_s^2)^2 + \frac{\Gamma_p^2}{2} M_p^2} + f_\omega \frac{(M_h^2 - M_s^2) - i \Gamma_\omega M_\omega}{(M_h^2 - M_s^2)^2 + \Gamma_\omega^2 M_\omega^2}$$

$$- i f'_\omega \frac{\sqrt{\lambda(M_\omega^2, M_h^2, m_\pi^2)} \Theta(M_\omega - m_\pi - M_h)}{4 \pi \Gamma_\omega M_\omega^2 \sqrt{4 M_\omega^2 m_\pi^2 + \lambda(M_\omega^2, M_h^2, m_\pi^2)}},$$

where $\lambda(M_\omega^2, M_h^2, m_\pi^2) = [M_\omega^2 - (M_h + m_\pi)^2][M_\omega^2 - (M_h - m_\pi)^2]$ and $\Theta$ denotes the unit step function. The couplings $f_s$, $f_p$, $f_\omega$ and $f'_\omega$ are parameters of the model. The first two terms of $F^p$ can be easily identified with the contributions of the $\rho$ and the $\omega$ resonances decaying into two pions. The Lorentz structure of the resonance propagators is already taken into account in Eq. (10). The masses and widths of the two resonances are taken from the PDG 66: $M_\rho = 0.776$ GeV, $\Gamma_\rho = 0.150$ GeV, $M_\omega = 0.783$ GeV, $\Gamma_\omega = 0.008$ GeV. The details of the resonance propagators could be also extracted from phase-shift analyses, as done in Ref. 21. In this case the contribution of the $\rho$ resonance would be

$$f_\rho \frac{- \tan \delta^1_m - i \tan^2 \delta^1_m}{\Gamma_\rho M_\rho (1 + \tan^2 \delta^1_m)}$$

where $\delta^1_m$ are the $\pi\pi$ phase shifts for the specific ($l,m$) channel. However, using $\delta^1_m$ from, e.g., Ref. 67 leads to no significant change compared to Eq. (25), especially considering the coarse level of accuracy of our model.

The third term in Eq. (25) comes from the decay of an $\omega$ resonance into three pions, of which the $\pi^0$ goes undetected, i.e., channel 4. Let’s introduce the momentum $P_\omega = P_h + P_0$, where $P_0$ is the momentum of $\pi^0$ and $P_h^2 = M_h^2$.

Taking for $\omega$ the usual Lorentz structure of a vector meson resonance, the evaluation of the correlator $\gamma$ involves the contraction

$$\gamma_\mu \left( - g^{\mu\nu} \frac{P_\omega P^{\nu}_\omega}{M_\omega^2} \right) R_\nu = - R + \frac{R \cdot P_0 (P_h + P_0)}{M_\omega^2} = - R \left( 1 + \frac{|\vec{P}_0|}{3M_\omega^2} \right).$$

In the last step we took into account the fact that $R$ has no timelike component and we have to integrate over $\vec{P}_0$. When performing the integration over $P_0$, we make a narrow-width approximation and we assume that the three pions are produced exactly at the $\omega$ mass ($M_\omega = M_\omega$). In this approximation, $|\vec{P}_0|$ is fixed, the last term of Eq. (30) becomes negligible, the contribution of channel 4 to the vertex turns out to be purely imaginary and occurs only at invariant masses lower than $M_\omega - m_\pi = 0.643$ GeV. Abandoning the narrow-width approximation has the consequence of smearing the invariant-mass distribution and allowing pairs to appear at invariant masses higher than 0.643 GeV, as well as giving a real part to the third term of Eq. (25).

Note that we sum the three contributions in Eq. (25) at the amplitude level. This is the first instance where the assumption of equal spectators has a direct consequence, and deserves further comments. Channels 2, 3 and 4
can interfere if $X_2 = X_3 = X_4$. In general, only a fraction of the total events will fulfill this requirement. On
the contrary, since we have a single spectator for all channels this is always the case in our model. That’s why we add
up the amplitudes in Eq. (28). As we shall see in the next section, the effect of these interferences in the unpolarized
fragmentation function is in any case quite small, due to the small contribution of channel 3 and the small overlap
between channels 2 and 4. However, a similar problem will show up also in the calculation of the function $H^3_1$, with
more relevant consequences, as we shall see in Sec. VII.

Finally, we felt the need to use $z$-dependent $A$-cutoffs to have an acceptable description of the data. We used the
following ansatz:

$$\Lambda_{s,p} = \alpha_{s,p} z^{\beta_{s,p}} (1 - z)^{\gamma_{s,p}}. \quad (31)$$

The total number of parameters of the model is thus 12: 3 parameters for the form-factor cutoff $\Lambda_s$, 3 parameters
for the cutoff $\Lambda_p$, the couplings $f_s$, $f_p$, $f_\omega$ and $f'_\omega$, the mass of the spectator, $M_s$, and the mass of the
fragmenting quark, $m$. However, in the following we shall always assume $m = 0$.

### IV. COMPARISON WITH PYTHIA AND PARAMETERS FIT

In order to fix the parameters of the model, we compare it to the output of the PYTHIA event generator [53]
tuned for HERMES [54]. The events are generated in $4\pi$. Exclusive channels are dropped. The standard HERMES
semi-inclusive DIS cuts are applied, in particular $Q^2 > 1 \text{ GeV}^2$, $0.1 < y < 0.85$, $0.023 < x < 0.4$, $W^2 > 4 \text{ GeV}^2$
and the momenta of the pions ($|\vec{P}_1|, |\vec{P}_2|$) are constrained to be larger than 1 GeV. The counts per $M_h$-bin are proportional
to the cross section of Eq. (16) times $2M_h$ (since the cross section in the former equation is differential in $dM_h^2$),
integrated over $y$, $x$, $\phi_R$, $\phi_S$, and further over $0.2 < z < 0.8$. For the counts per $z$-bin, we integrated the cross section
over $0.3 \text{ GeV} < M_h < 1.3 \text{ GeV}$. In Fig. 4 the number of counted dihadron pairs is presented binned in $M_h$ (200 bins from 0.3 to 1.3 GeV) and $z$ (200 bins from 0.2 to 0.8). From the total counts, we excluded the contributions from $\eta$ and $K^0$, i.e., channels 5 and 6 (see Fig. 2), because they are not relevant for our purposes. The lowest dark-gray histogram represents the sum of the $\rho$ and $\omega$ contributions (channels 2, 3, and 4), assumed to describe the whole $p$-wave contribution. The light-gray histogram in the middle is the “background” contribution, i.e. channel 1, representing the $s$-wave contribution. The upper histogram is the sum of the other two and corresponds to the total counts minus channels 5 and 6.

Instead of leaving all parameters of the model free, for sake of simplicity we assumed the fragmenting quark to be
massless. We take the spectator mass to be proportional to the pair’s invariant mass. The number of free parameters
we used is then 11.

The $\chi^2$ minimization was performed using MINUIT. The $\chi^2$ function was defined as the square of the difference
between the expected number of events in the bin and the measured value, divided by the expected number (equivalent
to assigning a statistical error equal to the square root of the number of events in the bin). The resulting $\chi^2/d.o.f$
is very high, about 25. However, we believe that the main characteristics of the $M_h$ and $z$ shapes of the unpolarized
fragmentation functions are qualitatively well described. The result of the fit for the $s$ and $p$ wave is shown on top of
the PYTHIA output in Fig. 4.

The values of the parameters obtained by the fit are:

$$\alpha_s = 2.60 \pm 0.05 \text{ GeV}^2, \quad \beta_s = -0.751 \pm 0.008, \quad \gamma_s = -0.193 \pm 0.004, \quad (32)$$
$$\alpha_p = 7.07 \pm 0.11 \text{ GeV}^2, \quad \beta_p = -0.038 \pm 0.003, \quad \gamma_p = -0.085 \pm 0.004, \quad (33)$$
$$f_s = 1197 \pm 2 \text{ GeV}^{-1}, \quad f_p = 93.5 \pm 1.6, \quad f_\omega = 0.63 \pm 0.03, \quad (34)$$
$$f'_\omega = 75.2 \pm 1.2, \quad M_s = (2.97 \pm 0.04) M_h. \quad (35)$$

The coupling constants are fixed modulo an overall normalization factor which depends on the luminosity and is
irrelevant for asymmetry calculations. The sign of the coupling constants is also not fixed, but the relative sign of $f_p$, $f_\omega$ and $f'_\omega$ is (see below).

In the $p$-wave channel, our model deviates significantly from the generated spectrum in the region around 0.6 GeV,
substantially increasing the $\chi^2$. This is due to the interference between channels 2 and 4, which is not included in the
Monte Carlo generator. At the same time, in the $s$-channel the curve obtained from our model underestimates the
data in the same region. Thus, the sum of the two curves is in good agreement with the total generated spectrum, to

---

4 To perform the fit, we neglected the last cut.
which the Monte Carlo generator is actually tuned. The agreement would be improved further if the contribution of the $\omega$ were extended at higher invariant masses by leaving the narrow-width approximation for the $\omega$ resonance and smearing the step function in Eq. (28). Note that the interference is in this case constructive because the signs of the couplings $f_p$ and $f'_\omega$ have been taken equal. If the two couplings were taken opposite, then a destructive interference would take place and the model would underestimate the $\rho$-wave contribution; dashed line: $s$-wave contribution; dotted line: sum of the two. The contributions of the $\eta$ and $K^0$ have been excluded.

V. PREDICTIONS FOR POLARIZED FRAGMENTATION FUNCTIONS AND TRANSVERSE-SPIN ASYMMETRY

Using the parameters obtained from the fit we can plot the results for the fragmentation functions $D_{1,tt}$, $H^q_{1,ot}$, and $D_{1,ot}$. The function $D_{1,tt}$ is a pure $p$-wave function. It depends on $|F|^2$, the modulus square of Eq. (28), and has a behavior very similar to $D^p_{1,oo}$, the $p$-wave part of $D_{1,oo}$. In Fig. 5 (a) we plot the ratio between $D_{1,tt}$ and $D_{1,oo}$, integrated separately over $0.2 < z < 0.8$. In Fig. 5 (b) we plot the same ratio but with the two functions multiplied by $2M_h$ and integrated over $0.3 \text{GeV} < M_h < 1.3 \text{GeV}$. In the same figures, the dotted lines represent the positivity bound $|\vec{R}|/M_h$.

\[
-\left| \vec{R} \right|/M_h \leq \frac{3}{2} D^p_{1,oo} \leq 3D^p_{1,oo}. \tag{36}
\]

The functions $D_{1,ot}$ and $H^q_{1,ot}$ arise from the interference of $s$ and $p$ waves, i.e. from the interferences of channels 1-2, 1-3, and 1-4, proportional to the product $(f_s f_p)$, $(f_s f_\omega)$, $(f_s f'_\omega)$, respectively. Since the relative sign of $f_s$ and the $p$-wave couplings is not fixed by the fit, we can only predict these functions modulo a sign. For the plots, we assume that the $p$-wave couplings have a sign opposite to $f_s$ (as suggested by the sign of preliminary HERMES data).

In Fig. 4 (a) we plot the ratio between $-|\vec{R}|/M_h H^q_{1,ot}$ and $D_{1,oo}$, integrated separately over $0.2 < z < 0.8$. In Fig. 4 (b) we plot the same ratio but with the two functions multiplied by $2M_h$ and integrated over $0.3 \text{GeV} < M_h < 1.3 \text{GeV}$. In the same figures, the dotted lines represent the positivity bound $|\vec{R}|/M_h$.

\[
|\vec{R}|/M_h H^q_{1,ot} \leq \frac{3}{8} D^p_{1,oo} \left( D^p_{1,oo} - \frac{1}{3} D_{1,tt} \right). \tag{37}
\]

As is evident, there are two main contributions:

- the interference between channel 1 ($s$-wave background) and the imaginary part of 2 ($\rho$ resonance), with a shape peaked at the $\rho$ mass, i.e. roughly proportional to the imaginary part of the $\rho$ resonance in Eq. (28);
The two contributions have comparable size and are large. At this point, we want to stress once more that our model assumptions imply that the above channels can interfere in a complete way, since the spectators $X_1$, $X_2$ and $X_4$ are the same. As already argued before, it is likely that only a fraction of the $X_2$ and $X_1$ states interfere, and so does a (in general different) fraction of the $X_4$ and $X_1$ states. This could decrease the sizes of the two “peaks” of Fig. 6 (a) and accordingly the overall size of the curve in Fig. 6 (b). This is beyond the reach of our model in its present form, but could be a way to proceed when fitting data related to $H_{1, ol}^\chi$.

In Fig. 7 (a) we plot the ratio between $-D_{1, ol}$ and $D_{1, oo}$, integrated separately over $0.2 < z < 0.8$. In Fig. 7 (b) we plot the same ratio but with the two functions multiplied by $2M_h$ and integrated over $0.3 \text{ GeV} < M_h < 1.3 \text{ GeV}$. The dotted line in Fig. 7 (a) represents the positivity bound \([55]\) (in the second plot the bound lies beyond the plot range)

$$D_{1, ol} \leq \sqrt{\frac{3}{4} D_{1, oo}^p \left( D_{1, oo}^p + \frac{2}{3} D_{1, ll} \right)}.$$  

(38)

In this case, the function $D_{1, ol}$ receives basically only one contribution, namely from the interference between channel 1 (s-wave background) and the real part of 2 ($\rho$ resonance). In fact, its shape has a sign change at the $\rho$ mass and is roughly proportional to the real part of the $\rho$ resonance in Eq. \([28]\). Channel 3 is negligible as in the previous case, while channel 4 plays no role now because we assumed it to be purely imaginary.
Next we compute the asymmetry defined in Eq. (18), integrated over all variables but one. In Fig. 8 (a) we plot

\[ A_{UT}^\sin(\phi_R + \phi_S)(x) = c \int_{0.02}^{0.08} dy \int_{x_{min}}^{x_{max}} dx \frac{1 - y^2 x^2/4}{y^2 (1 + y^2)} 4 \left[ (h^u(x) - h^d(x)) + (h^d(x) - h^u(x)) \right] \]

and in Fig. 8 (b) we plot

\[ A_{UT}^\sin(\phi_R + \phi_S)(z) = c \int_{0.02}^{0.08} dz \int_{0.5}^{1} dM_h 2M_h |\vec{R}_1/M_h H_{1,ot}^u(z, M_h^2)\]

where

\[ c = \frac{\pi}{4} \int_{0.02}^{0.08} dy \int_{x_{min}}^{x_{max}} dx \frac{1 - y^2 x^2/4}{y^2 (1 + y^2)} 4 \left[ (f^u(x) + f^d(x)) + (f^d(x) + f^u(x)) \right] \]

We neglected strange quark contributions. The fact that the \( d \) and \( \bar{u} \) transversity distributions enter with an opposite sign is due to the symmetry properties of the fragmentation functions. As already discussed in Sec. III, the fragmentation function \( H_{1,ot}^u \) is the same for all quarks, but the sign of \( \sin(\phi_R + \phi_S) \) changes for \( d \) and \( \bar{u} \).

In Fig. 8 (c) we plot

\[ A_{UT}^\sin(\phi_R + \phi_S)(x) = c' \int_{0.02}^{0.08} dz \int_{0.02}^{0.08} dy \int_{x_{min}}^{x_{max}} dx \frac{1 - y^2 x^2/4}{y^2 (1 + y^2)} 4 \left[ (f^u(x) + f^d(x)) + (f^d(x) + f^u(x)) \right] \]

where

\[ c' = \frac{\pi}{4} \int_{0.02}^{0.08} dz \int_{0.5}^{1} dM_h 2M_h |\vec{R}_1/M_h H_{1,ot}^u(z, M_h^2)\].

The choices of the integrations boundaries for \( x, y, z \) and \( M_h \) are inspired by the HERMES cuts. We took \( s = 56.2 \text{ GeV}^2 \)

\[ x_{min} = \text{Max}[0.023, Q_{min}^2/(y(s - M^2))], \]

\[ x_{max} = \text{Min}[0.4, 1 - (W_{min}^2 - M^2)/(y(s - M^2))], \]

\[ y_{min} = \text{Max}[0.1, Q_{min}^2/(x(s - M^2)), (W_{min}^2 - M^2)/(1 - x)(s - M^2))]. \]

For the unpolarized parton distribution functions we take the parameterization of Ref. 71. For the transversity distribution function, we take the estimates of Refs. 35, 68, 62, 70. The sign of the preliminary data indicates that the \( s \)-wave and \( p \)-wave couplings should have opposite signs and thus \( H_{1,ot}^u \) should be negative. The asymmetry obtained

FIG. 7: Model prediction for the ratio \(-D_{1,ot}/D_{1,oo}\): (a) as a function of \( M_h \), (b) as a function of \( z \). The overall sign of \( D_{1,ot} \) depends on the choice made on the sign of \( H_{1,ot}^u \). The dotted lines represent the positivity bounds of Eq. 38.
from our model appears to overestimate the preliminary HERMES data [48] by about a factor 3–4. This probably indicates that the model overestimates in general the effect of interferences. Apart from the overall normalization, the height of the bump around $M_h \approx 0.5$ GeV seems to be too big relative to the $\rho$ peak, which is probably due to the fact that not all the $\pi^+\pi^−$ pairs in channel 4 should be considered in $p$ wave. However, in order to make more conclusive statements it is necessary to wait for HERMES final data. Obviously, it would be better to compare our model with an observable where $H_{1T}^c$ can be isolated, e.g., in $e^+e^-$ annihilation at BELLE [51].

In Fig. [9] we plot the same asymmetry as before, but for the kinematics of the COMPASS experiment. We assumed the same cuts as before and change only the value of $s$. The size of the $M_h$- and $z$-dependent asymmetries is smaller than at HERMES. This is due to the sensitivity of COMPASS to lower values of $x$, where models predict transversity to be small, while the unpolarized distribution functions are big. Due to the same reason, there is a much larger difference among the models, as they differ substantially at low $x$. The asymmetries could be enhanced if the low-$x$ region is excluded from the integration.

The COMPASS collaboration has also presented preliminary data of the above asymmetry for a deuteron target [49]. We plot our prediction in Fig. [10]. The different isospin structure of the target, combined with that of the fragmentation functions in our model, decreases the asymmetry. The $x$-dependent asymmetry is less than half of that for the proton target, while the $M_h$- and $z$-dependent asymmetries are about 10 times smaller than for the proton target.

\footnote{Note that the preliminary measurements of COMPASS correspond to $-A_{UT}^{\sin(\varphi_R+\varphi_S)}$.}
VI. CONCLUSIONS

In this paper we presented a model for the process $q \rightarrow \pi^+\pi^-X$ at invariant mass $M_h \lesssim 1.3$ GeV. We used a “spectator” model, where the sum over all possible intermediate states $X$ is replaced by an effective on-shell state. Using this model we calculated the fragmentation functions that can be defined at leading twist when considering the “spectator” model, where the sum over all possible intermediate states contributes.

We fixed the values of the parameters of the model by comparing the unpolarized fragmentation function $D_{p,1\ell\ell}$ with the output of the PYTHIA event generator [53] tuned for HERMES [54]. The main characteristics of the $M_h$ and $x$ shapes of $D_{p,1\ell\ell}$ are particularly well described.

We made predictions for the fragmentation functions $D_{1,\ell\ell}$, $D_{1,\ell\rho}$, and $H_{1,\ell\rho}$. The first one is a pure $p$-wave function, it is found to be positive, about 50% of the unpolarized fragmentation function and with peaks at the $\rho$ mass and at around $M_h \approx 0.5$ GeV, where the $\omega$ decaying into three pions gives a large contribution.

The function $D_{1,\ell\rho}$ arises from the interference between $s$ and $p$ waves. Since in our model we assumed the $s$ wave to be purely real, this function turns out to be proportional to the real part of the $p$ wave and in particular displays a sign change at the $\rho$ mass. The size of the function is small, in particular when integrated over the invariant mass, due to the sign change. Our model cannot predict the overall sign of the function.

The function $H_{1,\ell\rho}$ also arises from the interference between $s$ and $p$ waves, but is proportional to the imaginary part of the $p$ wave, i.e., it has peaks at the $\rho$ mass and around $M_h \approx 0.5$ GeV, due to the contribution of the $\omega \rightarrow 3\pi$ channel. Its size is about 30% of the unpolarized fragmentation function. Our model cannot predict the overall sign of the function.

The function $H_{1,\ell\rho}$ is of particular interest because in two-hadron-inclusive deep inelastic scattering off transversely polarized targets it gives rise to a single-spin asymmetry in combination with the transversity distribution function. Therefore, it could be used as an analyzer for this so far unknown distribution function. We estimated this single-spin asymmetry at HERMES kinematics using four different models for the transversity distribution function. We found the asymmetry to be of the order of 10% on average. The sign of the preliminary HERMES measurements suggests that $H_{1,\ell\rho}$ should be negative. The measurement indicates that the asymmetry in our model is about 3-4 times bigger than the data. This probably means that our model overestimates the effects of interferences. However, final experimental results are needed to make more reliable comparisons.

For COMPASS kinematics, the enhanced sensitivity to the portion of phase space at very low $x$ induces a reduction in the spin asymmetry with respect to HERMES, which can largely differ depending on the model for transversity. For the deuteron target, the particular isospin structure, combined with that of the fragmentation functions in our model, induces a further reduction such that the resulting asymmetry is much smaller than for the proton, in agreement with preliminary data of the COMPASS collaboration.

Acknowledgments

Useful discussions with P. van der Nat, C. A. Miller, G. Schnell, E. C. Aschenauer, are thankfully acknowledged. We are particularly grateful to the HERMES Collaboration for providing us with the PYTHIA output. We are grateful to M. Stratmann, V. Korotkov, P. Schweitzer and M. Wakamatsu for making their predictions for the transversity distribution function available. This work is partially supported by the European Integrated Infrastructure Initiative...
