Abstract

Background: In the last years an increasing number of patients have sought for comfortable and aesthetic alternatives to fixed appliances. Aligners, due to the protection against tooth wear, can be compared to occlusal splints used in patients suffering from sleep bruxism (SB). The aim of the study was to analyze the effects of clear aligners on SB episodes using a validated portable device (Bruxoff®, OTBioelettronica, Torino, Italy) allowing a simultaneous recording of electromyographic signals from both the masseter muscles as well as heart frequency to evaluate variation on SB activity.

Methods: Forty patients were analyzed for the study. Twenty of them were assigned to orthodontic treatment with clear aligners (Invisalign®, Align Technology). The other twenty patients were used as control group observed for a period of twelve months. Intra-group and inter-group variances were analyzed by using a two-way ANOVA test. For each analysis a $P < 0.05$ was set.

Results: After the first month of clear aligners therapy, all patients in the case group showed a significant reduction in the number of SB episodes ($P < 0.05$). However, after three months SB values returned to baseline levels. The number of tonic contractions were reduced even after three months of orthodontic treatment ($P < 0.05$).

Conclusions: While clear aligners seem to be capable to reduce clenching, i.e. occlusal load, in SB patients, the grinding activity seems to be not influenced by those appliances at least in the short term of the present investigation.

Keywords: Sleep Bruxism, Clear Aligners, Orthodontics, Surface Electromyography, Masseter Muscle, Heart Rate

1. Background

Sleep bruxism (SB) is a sleep-related motor disorder characterized by (rhythmic) involuntary phasic or tonic (sustained) motor activity in the masticatory muscles (e.g. masseter, temporalis) during sleep (1). SB shows a mean prevalence of 14% - 20% in adolescents and 12.8% in adults, with no gender differences and a tendency to decline with increasing age (1, 2). Most of the orthodontic patients are part of this population (3, 4). In a recent systematic literature review4 dental malocclusion presents moderate association with SB in adolescents and, moreover, the presence of parafunctions such as bruxism may be a predisposing factor for temporo-mandibular disorders (TMDs) (5). Since the association between SB and TMDs with painful sensation has been stated (6-8) and occlusal overload induced by SB may be a co-factor (9-12), the orthodontic treatment of malocclusion in patients suffering from SB may be useful in controlling, at least, one of the factors involved in the multifactorial etiology of TMDs. In the last years, the use of clear aligners in orthodontic treatment has reached an important role even in complex cases (13, 14). Such disposals, due to the protection against tooth wear, can be compared to occlusal splints used in patients suffering from SB (15-19). Unfortunately, no literature data are available about the efficacy and efficiency of these orthodontic disposals in modifying or reducing the number of SB episodes. The study was designed to answer the clinical research question "is sleep bruxism influenced by orthodontic treatment with clear aligners?"

2. Objectives

The source underlying the study was that a positive answer to the above question could lead to the possible introduction of a specific orthodontic treatment for patients suffering from SB with a possible modulation of the number of SB episodes per night.

3. Methods

This observational prospective study, involved 53 subjects (27 m, 25 f, 28 ± 13 years) selected among patients referring to the Orthodontics Unit of the Dental School of the University of Torino in the period February-December 2015 requiring an orthodontic treatment. All the subjects were screened for sleep bruxism with a validated portable device (Bruxoff ®, OT Bioelettronica, Torino, Italy) (20-24). On the basis of this evaluation the subjects were divided into two groups: the case group composed by 20 patients (7 m, 13 f, 25 ± 10 years), and the control group composed by 33 patients (20 m, 13 f, 26 ± 10 years). The control group was a "waiting list" control group, without any form of treatment for the following 6 months. During the follow-up period, 13 patients from the control group (5 m, 8 f, 28 ± 7 years) withdraw from the study, obtaining a final control group formed by 20 patients (15 m, 5 f, 29 ± 12 years). The study was conducted according to the Declaration of Helsinky, and each subject was aware to withdraw from the experiment at any time. A written informed consent was obtained by each patient. The study was approved by the Local ethical committee (#3742015).

3.1. Inclusion and Exclusion Criteria

The inclusion and exclusion criteria are resumed in Table 1.

Table 1. Inclusion and Exclusion Criteria

Inclusion Criteria	Exclusion Criteria
Patients aged from 13 to 30 years	Previous or current SB treatment
Patients requiring orthodontic treatment	Presence of prosthodontics rehabilitations
Absence of medications	Missing teeth, with the exception of the third molars
	Periodontal disease
	Group II and/or Group III TMDs (articular TMDs)
Avoiding alcohol, nicotine or caffeine during night recordings	Medical history of neurological, mental or sleep disorders (e.g. periodic leg movements, insomnia)
	Post-traumatic patients
	Previous or current orthodontic treatment
	Obstructive sleep apnea syndrome (OSAS)

3.2. Clinical Records

Dental panoramics, latero-lateral radiograms and dental casts were taken for all the 20 patients before to start the orthodontic treatment with clear aligners.

3.3. SB Diagnosis and Monitoring

A validated portable device for SB diagnosis (Bruxoff ®, OT Bioelettronica, Torino, Italy) with three channels was used for recording (20-24). Two channels were used to acquire surface electromyography (sEMG) from the masseter (bilaterally), and the third channel was used to acquire the heart frequency (HF). The three signals were sampled at 800 Hz, with 8 bit resolution.

A microSD card was used to store the data as a binary file. The sEMG channels were filtered between 10 and 400 Hz with gain 4300. The electrocardiographic (ECG) channel was filtered between 15 and 160 Hz with gain 700. Surface EMGs from the masseter muscles (both sides) were detected with disposable bipolar concentric electrodes (Code®, Spes Medica, Battipaglia, Italy), with a radius of 16 mm and with detection site made of AgCl (Figure 1). The concentric-ring systems of the Code electrodes show higher spatial selectivity with respect to the traditional detection systems and reduce the problem of electrode location since they are invariant to rotations and reducing EMG crosstalk (25). The heart frequency was perceived with a disposable bipolar electrode located on the left side of the thorax just below the pectoral muscles. At first, the subjects were asked to accomplish three maximum voluntary clenching (MVC), 3 seconds each and separated by 10 seconds of rest. The greatest of the MVC measures was used to normalize the EMG values as a percent of MVC. Previous studies showed a high sensitivity (92.3%) and specificity (91.6%) of the portable device when the cut-off was set at 4 SB episodes per hour accordingly to published criteria (22). Furthermore a reliability study of the Bruxoff demonstrated a good reproducibility for SB episodes per night, SB episodes per hour, and heart frequency20. Scoring on the Bruxoff recordings was automatically performed by dedicated software (Bruxmeter ®, OT Bioletton-ica, Torino, Italy).

The SB episode can be classified by the software, if the sEMG burst is greater than 10% MVC and if it immediately follows (1 - 5 seconds interval) a heart rate increase of 20% with respect to the baseline accordingly to the existing literature (25-27). Moreover, instrumental evaluation allowed to identify specific sEMG signals: tonic, phasic and mixed.

3.4. Night Recordings With Bruxoff Device

Multiple night recordings with the Bruxoff® device were made both for case and control groups. The first night was used as accommodation session. Then other recordings were made at screening time, at the beginning of orthodontic treatment (only for case group) (T0), after 1 month (T1) and after three months (T2). The device

The concentric-ring systems of the Code electrodes show higher spatial selectivity with respect to the traditional detection systems and reduce the problem of electrode location since they are invariant to rotations and reducing EMG crosstalk. At the top a schematic representation of the electrode location over the masseter muscle is shown. Black line: gonial angle-cantus line used as anatomical landmark.

was used and mounted without technical assistance, after prior training, at home. Written instructions were provided and a night-time telephone number to call in the event of difficulties.

3.5. Orthodontic Treatment

Orthodontic diagnosis was completed by the digital scanning of dental impression through dedicated software (Clincheck® Align Technology Inc. San Jose, California (USA)). This software allowed virtual simulations of orthodontic movements and guided the realization of custom-made clear aligners for each patient. All patients were provided with a precise sequence of clear aligners, to be replaced every two weeks, according to the standard protocol (28). Every month each patient was controlled in order to check compliance, orthodontic tooth movement and to perform routine inspections.

3.6. Statistical Analysis

The number of SB episodes of every patient, recorded during the 3 time points (T0, T1, T2), was collected. The sample passed the Kolmogorov-Smirnov normality test. Intragroup and inter-group variances were analyzed with two-way (variables time and treatment) ANOVA test. All statistical procedures were performed with the software statistical package for the social science v. 23.0 (SPSS 23.0®, IBM, Milan, Italy). Significance was set at $P < 0.05$.

4. Results

The two groups of patients were followed for a period of three months and evaluated in three different moments (T0: screening, T1: evaluation after 1 month, T2: evaluation after three months) with instrumental (Bruxoff®) recordings. The statistical analysis demonstrated that the number of SB episodes significantly reduced after one month follow-up in the case group ($P < 0.05$, 95% CI) (Figure 2). However, at T2 evaluation the number of SB episodes in the case group raised up to T0 levels with no statistical differences between T0 and T2 ($P > 0.05$, 95% CI). The number of total tonic contractions of the masseters muscles in the case group reduced in a significant way after one and three months ($P < 0.05$, 95% CI) (Figure 3), although the number of tonic contractions related to SB episodes in the case group, after a significant reduction in the first month ($P < 0.05$, 95% CI), raised up to T0 levels with no statistical differences between T0 and T2 ($P > 0.05$, 95% CI) (Figure 4). Phasic and mixed contractions of the masseters muscles showed no statistical differences at T1 and T2 points neither inter-groups nor intra-groups ($P > 0.05$, 95% CI).

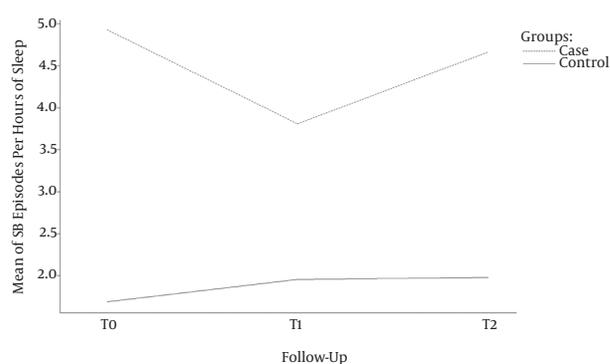

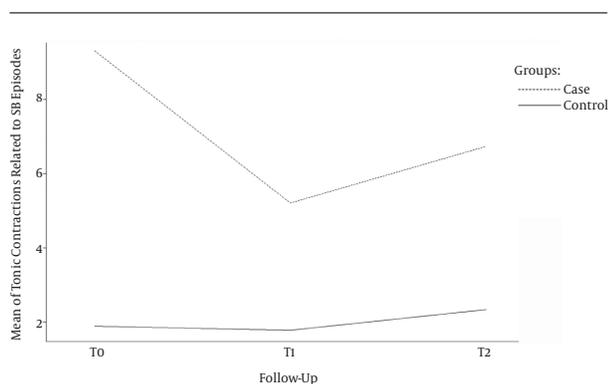

Figure 2. Number of SB Episodes Per Hour of Sleep

5. Discussion

In the last years, the use of clear aligners to obtain orthodontic tooth movement grew up significantly in order
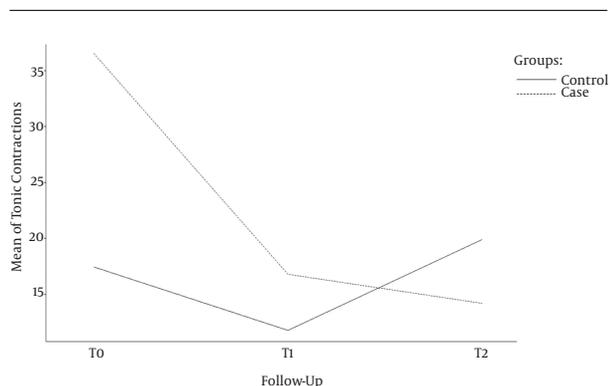

Figure 3. Mean of General Tonic Contractions

Figure 4. Mean of Tonic Contractions Related to SB Episodes

the number of SB episodes per hour of sleep such as for the number of masseters contractions (bursts per hour of sleep) in polysomnographic recordings. According to Manfredini et al. (2015) (15) it seems that almost every type of OA is in some way effective to reduce SB activity. This may suggest the existence of a possible 'novelty effect' associated with the use of an OA, which leads to a reduction in sleep-time masticatory muscles' activity, possibly due to the transient need for reorganizing motor unit employment. All patients recruited for this study were selected according to the presence or absence of SB. All of them did not present clinical signs or symptoms of SB, but after instrumental recording with Bruxoff® device, for the 62% of them severe SB was diagnosed. Moreover, clinical signs and symptoms of SB cannot be used for definite diagnosis (2, 22, 23), especially after analyzing preliminary data from this study. Since the association between SB and TMDs with painful sensation has been stated (6-8) and occlusal overload induced by SB may be a co-factor (9-12), aligner treatment should be considered as a possible option to treat patients suffering from SB with need for orthodontic treatment. In this light the use of validated portable devices (22) for the diagnosis of SB should be introduced in the orthodontics clinical setting at least as screening devices.

5.1. Conclusions

While clear aligners seem to be capable to reduce clenching, i.e. occlusal load, in SB patients, the grinding activity seems to be not influenced by those appliances at least in the short term of the present investigation.

Acknowledgments

Footnote

to answer the request for possible comfortable and aesthetics alternatives to traditional fixed appliances. Such disposals, due to the protection against tooth wear, can be compared to occlusal splints used in patients suffering from SB. Results from the present study showed that, on a short term basis, the use of clear aligners can reduce tonic contractions (i.e. clenching) but not phasic (i.e. grinding contractions). Furthermore the number of SB episodes showed a significant reduction during the first month of treatment, while after three months no significant differences were observed with respect to the baseline. Interestingly 38% of the patients treated with Invisalign® aligners were low intensity bruxers while the 62% were high frequency bruxers at T0 according to Rompré et al. (2007) (29). After three months of treatment the 54% of patients were low frequency bruxers while the 46% were high frequency bruxers. Accordingly to the statistical analysis the percentage reduction could be associated to the significant reduction of SB related clenching contractions. According to Dubé et al. (2004) (30), patients wearing oral appliances (OAs) significantly reduced after one month
